Unusual Hydatid Cyst of the Breast: A Case Report

Abstract
The hydatid cyst of the breast is a rare pathology even in countries endemic to tuberculosis, however there remains a differential diagnosis evoked in front of any breast tumor. the clinic, mammography and ultrasound sometimes allow us to suspect the hydatid nature of the lesion. The definitive diagnosis remains histological and the treatment is always surgical. We report an observation of a breast hydatid cyst discovered incidentally.

Keywords: Hydatid Cyst; Tuberculosis; Breast

Introduction
Hydatid cyst is a parasitic disease caused by the development in the body of the larval form of a tapeworm called Echinococcus granulosus [1]. It was still considered a pulmonary pathology. However, nearly 17.9% of tuberculosis cases have extrapulmonary manifestations [2]. Breast and skin are considered rare sites of extra pulmonary mycobacterial infection, accounting for 0.1% to 0.5% of all Tuberculosis cases respectively [3]. Patients usually present to the hospital with a palpable, painless lump in the breast being difficult to differentiate it from other tumor lesions of the breast. Only a few cases are published in the literature and the majority of reported cases were diagnosed postoperatively [4]. From one case, we recall the epidemiological, diagnostic and therapeutic aspects of this pathology.

Case Report
A 59-year-old patient, rural resident, menopausal for 5 years, without particular pathological history, consults for swelling in the right breast. The onset of symptoms goes back 5 months by auto palpation of a nodule in the right breast associated with a progressive increase in its volume associated two months later with mastodynia, without nipple discharge, without local inflammatory sign.

Clinical examination shows 2 masses occupying the entire upper outer quadrant of the right breast, respectively 8 cm, 4 cm in diameter and prolapsing in the axillary region, of soft consistency, well limited, mobile and painless, without inflammatory phenomenon of the skin integuments opposite. There is no axillary or supraclavicular lymphadenopathy, nor nipple discharge (Figure 1). Radiological explorations (mammography + ultrasound) (Figure 2) carried out objectified:

A voluminous opacity of the QSE of the dense and well limited right breast corresponding on ultrasound to two cystic masses of the QSE and the right axillary hollow. The first measures 66 × 84 mm in transverse diameter and has a thin wall and anechoic content classified by ACR2 BIRADS. The second measures 49 × 47 mm in transverse diameter in the axillary hollow and has ultimately echogenic content with a sloping portion producing the appearance of pseudo vegetation classified ACR3 BIRADS. The two masses are not vascularized by Doppler.

An abdominal ultrasound, a chest x-ray, as well as a biological blood test (complete blood count, ionogram) performed is completely normal. A fine needle aspiration of the cyst only showed the presence of altered polynuclear, without evidence of tumor cells. Treatment consisted of surgical excision such as perikystectomy (Figure 3), and pathology examination demonstrated breast hydatidosis.

Discussion
Hydatid disease is a cyclozoosnosis caused by the larvae (metacestodes) in the stages of cestodes (tapeworms) belonging...
to the genus Echinococcus and the family Taenia. The disease exists in two forms: the larval stage (metacestode) and the adult stage (tapeworm). Parasites are perpetuated in life cycles with carnivores (dogs and wild canines) as definitive hosts. Humans are the accidental intermediate host (dead end) and animals (herbivores and omnivores) are both intermediate and definitive hosts [5]. The adult E. granulose is a worm, when infected it produces eggs passed in the stool. Eggs ingested by intermediate hosts like cows, sheep, and humans release an embryo into the duodenum, which enters the intestinal lining and enters the portal circulation [6,7]. The liver acts as a first filter and shuts down about 75%, while the lungs, the second filter, shut down about 10% and only 15% of embryos are free to develop cysts in others organs of the body [6]. According to Barret and Thomas, 60% of cysts are found in the liver, 30% in the lungs, 2.5% in the kidneys, 2.5% in the heart and pericardium, 2% in the bones, 1.5% in the spleen, 1% in the muscle and 0.5% in the brain [8,9]. The embryo develops into a unilocular cyst [10].

Hydatid breast disease is extremely rare even in endemic areas; it may be the sole primary site or part of disseminated hydatidosis. Usually, the patient presents with a painless breast mass, which slowly increases in size without regional lymph node involvement. It usually affects women between the ages of 30 and 50. Clinically it could mimic a fibroadenoma, phyllodes tumors, chronic abscesses, or even carcinomas. So hydatid cyst of the breast should be included in the differential diagnosis of breast tumors especially in endemic areas [8,11,12] typically appears as a nodule of firm or persistent consistency, of variable size, with clear contours, mobile and often painless. It is sometimes calcified and without inflammatory phenomenon or lymphadenopathy. The cyst is infected poorly limited and pseudotumoral in 5% of cases thus simulating an abscess or possibly a malignant tumor [13,14].

Paraclinically, mammography and ultrasound may be helpful but not conclusive. Mammography may show a homogeneous, well-circumscribed lesion with ring-shaped structures within the mass [15]. When infection occurs secondarily, it is difficult to distinguish between hydatid cyst and breast abscess by mammography [16]. Ultrasound can visualize the cyst and define five types according to the Gharbi classification [17]. Types II and III hydatid cysts have more specific diagnostic imaging properties than other types. Multiple daughter cysts separated by a fluid matrix containing a mixture of broken daughter vesicle membranes, scolices and hydatid content of mixed echogenicity can give rise to a "wheel-spoke" appearance. Separation of the ruptured endocyst from the ectocyst layer leads to a floating membrane which gives the sign of the water lily [16]. However, less characteristic aspects can be diagnosed, raising suspicion of other pathologies, in particular tumors. In these cases, magnetic resonance imaging finds its place by showing an appearance of a well-circumscribed cystic lesion associated with capsular enhancement suggestive of hydatid cyst [18].

The extension workup consists of looking for other localizations, particularly hepatic and pulmonary, by chest x-ray and abdominal.

ultrasound [19]. Fine needle aspiration is performed whenever the cystic nature of the mass has been suspected [20,21]. It is preferably performed under ultrasound. In this case, it brings back a "rock water" liquid pathognomonic of mammary hydatidosis. In the case of a superinfected hydatid cyst, the fluid becomes purulent, and therefore the puncture takes on its full diagnostic value.

Biologically, hyper-eosinophilia is nonspecific. Casoni’s intradermal reaction is only positive in 75% of cases. On the other hand, indirect immunofluorescence is a sensitive technique which gives good results [22].

The treatment of breast hydatidosis remains surgical. It consists of an excision of the cyst with per cystectomy which would protect against its break-in, a potential source of re-infestation. Some cases of postoperative recurrence have been reported but remain very rare. Only effective prophylaxis in order to break the cycle of E. granulose will allow this pathology to regress.

Conclusion

Although hydatid disease of the breast remains a rare localization of tuberculosis disease, it should nevertheless be considered as a differential diagnosis of breast tumors. Ultrasound, cytology and MRI play an important preoperative diagnostic role. Treatment is essentially based on surgical pericystectomy associated with medical treatment based on albendazole.
